Abstract

DNA molecular data are used to generate a phylogeny for the micropezid subfamily Taenipterinae. Thirty-two taenipterine species were sampled, including 10 of the 20 New World genera recognized by Steyskal, as well as one genus formerly treated as a synonym of *Poecilostylus* Hennig (*Hemichaeta* Steyskal). Five species from the Micropezinae were included as outgroups. A total DNA dataset of 4705 bp, including mitochondrial genes (12S and cytochrome *c* oxidase I (COI)) and nuclear coding genes (*wingless* and CAD), was analysed using maximum parsimony and Bayesian inference. The genus *Taeniptera* Macquart was found to be non-monophyletic with respect to the remainder of the Taenipterini analysed here. *Taeniptera* is restricted to the *Taeniptera trivittata* Macquart species group, *Mitromyia* Cresson is resurrected to contain the *Taeniptera grata* (Wulp) species group, and *Paragrallomyia* Hendel is resurrected to contain most species previously considered *Taeniptera*. *Poecilostylus* is recognized as a paraphyletic group awaiting further research.

Introduction

Most genera of Micropezidae are currently diagnosed using a few superficial characters, generally with a high level of variability and homoplasy. The tribe Taenipterini, for example, is broken into genera based on little more than the shape of the palpus and the type of arista, with most species with a bare arista included in *Taeniptera* Macquart (1835) on the basis of an “axe-shaped” palpus. These weak generic concepts need to be tested and either supported and clarified, or replaced by an alternative system of consistently diagnosable monophyletic taxa. We here use DNA data to reconsider the definition of the large genus *Taeniptera* and related Taenipterini.

Definition and diagnosis of Taenipterinae and Taenipterini

Taenipterinae is the most diverse subfamily of Micropezidae, and has a global distribution (minus Antarctica), with the greatest diversity occurring in the New World tropics. The subfamily is considered monophyletic based on a suite of apomorphies (ocelli displaced forward; sternopleural (katepisternal) bristles in a dense vertical fan of bristle-like hairs; subscutellum vestigial, not convex; epandrium bilaterally compressed (male); and surstyli absent (male)) (McAlpine 1998). Taenipterinae is usually divided into two tribes based on the length of cell cup and the length of vein CuA_2 relative to vein A_1+CuA_2 , with the short-celled genera (all Old World taxa and the following New World genera: *Mesoconius* Enderlein, 1922; *ZelatRACTODES* Enderlein, 1922; *Globopeza* Marshall 2005; *Metasphen* Frey, 1927; *Scipopus* Enderlein, 1922; *Pseudeurybata* Hennig, 1934; *Calosphen* Hennig, 1934; *Grallipeza* Rondani, 1850; *Planipeza* Marshall, 2008; *Cliobata* Enderlein, 1923; *Rainieria* Rondani, 1843; *Chaetotylus* Hendel, 1932; *Hoplocheiloma* Cresson, 1926) being placed in the Rainieriini of Cresson (1938) (=Grallipezini of Aczél 1951 and subsequent authors), and the exclusively New World long-celled genera (*Taeniptera*; *Hemichaeta* Steyskal, 1968; *Parasphen* Enderlein, 1922; *Ptilosphen* Enderlein, 1922; *Tenthes* Cresson, 1930; *Grallomyia* Rondani, 1850; *Poecilotylus* Hennig, 1934; *Plocoscelus* Enderlein, 1922; *Cardiacephala* Macquart, 1843) placed in the Taenipterini (Cresson 1938). We here consider the classification of the tribe Taenipterini, with a focus on the large genus *Taeniptera* and its close relatives. The New World Micropezidae have been studied by some of the leading dipterists of the 20th Century (Cresson 1938, Hennig 1934, 1935a,b, 1936, Aczél 1951, Steyskal 1967, 1968), yet several generic concepts are considered confluent and in need of redefinition; *Cliobata* and *Rainieria*; *Calosphen* and *Grallipeza*; *Pseudeurybata* and *Scipopus*; and, as will be discussed in this study, *Taeniptera* and *Poecilotylus* (Marshall 2010). *Taeniptera* (*sensu* Steyskal 1968) is currently the most diverse of these genera and one of the most problematic taxonomically. Originally erected by Macquart (1835) and redefined by Hennig (1934), this genus included 40 species in Steyskal's (1968) Catalog of Diptera South of the United States. A further four species have since been added (Albuquerque 1980, 1981; Steyskal 1986) without modification of Hennig's definition of the genus. Marshall (2010) followed Hennig (1934) in differentiating *Poecilotylus* and *Taeniptera* by the shape of the maxillary palpus and the frontal vitta, but added wing characters to the diagnoses and expressed doubt that these diagnoses reflected real monophyletic groups. The apparent dearth of consistent morphological characters to define Taenipterinae genera, possibly in part due to convergence on similar Hymenoptera models, suggests that the classification of this group could be improved with the use of additional, non-morphological character sets. Molecular data have proven useful for understanding generic relationships in other acalyprate families (Conopidae, Gibson et al. 2010; Sphaeroceridae, Kits et al. 2013; Diopsidae, Baker et al. 2001); we therefore set out to find nuclear and mitochondrial DNA characters of possible use in testing and defining generic boundaries within the Taenipterini.

Materials and methods

Taxon sampling

Ten of the 20 New World taeniapterine genera recognized by Steyskal (1967) (11 of the 23 New World taeniapterine genera recognized by Marshall, 2010; Marshall & Jackson, 2014) including six of nine Taeniapterini genera were sequenced, with a particular focus on species of *Taeniaptera* and *Poecilotylus* (Table 1). *Cardiacephala*, *Parasphen*, and *Tenthes* were not included due to a lack of suitably preserved material. *Cardiacephala* is likely closely allied with *Plocoscelus*, and *Parasphen* is very similar to *Ptilosphen*, but *Tenthes* shows no obvious affinities to other genera. Both genera of Micropezinae (*Micropeza* Meigen, 1800; *Cryogonus* Cresson, 1926) were included as outgroups.

DNA extraction and amplification

Total genomic DNA was extracted, amplified and sequenced following protocols from Gibson et al. (2010); however amplification reactions were carried out in 50 µL reactions, and Gibson et al. halved the volume of each component listed compared to our protocol. Primers and polymerase used for each gene sequenced can be found in Table 2.

DNA sequence editing and alignment

Sequence chromatograms were edited and contigs built using BioEdit ver. 7.0.9.0 (Hall 1999).

Sequence alignments for 12S rRNA were performed in ClustalX2 (Larkin et al. 2007) using the default settings. Preliminary alignments for COI, *wingless* and CAD were performed in ClustalX2 and alignments were then hand-aligned based on amino acid codons using MacClade ver. 4.06 (Maddison et al. 2003). For *wingless*, a 128 bp unalignable intron was identified at positions 378–506 and excised prior to analysis. No introns were found in the region of CAD sequenced (Moulton & Wiegmann 2004).

Final sequences were concatenated using TaxonDNA (Vaidya et al. 2011) and formatted for analysis.

Concatenated molecular dataset parsimony analysis

PAUP* 4.0 beta (Swofford 2003) was used to perform parsimony analyses. Each gene was partitioned and analysed individually, in addition to a total, concatenated analysis. Sequences were added randomly, and a heuristic search using TBR branchswapping for 1000 repetitions. Strict consensus trees were constructed from the most parsimonious trees returned by the analysis, and bootstrap (1000 resampling repetitions, each using 10 random addition sequence repetitions) and jackknife values (deletion frequency = 0.33, 1000 resampling repetitions, each using 10 random addition sequence

repetitions) were calculated. The full datasets and PAUP* 4.0 scripts used are available from the Dryad Digital Repository (<http://dx.doi.org/10.5061/dryad.nn20r>). Results of PAUP* 4.0 analyses were confirmed using a New Technologies Search including Sect. Search, Ratchet, Drift, and Tree Fusing with trees generated by randomly adding sequences in TNT: Tree Analysis Using New Technology (Goloboff et al., 2008).

Bayesian inference analysis

The total concatenated molecular dataset was analysed using Bayesian inference. Data were divided into four partitions (12S, COI, *wingless*, CAD). MrModeltest ver. 2.3 (Nylander 2004) was used to calculate evolution models of each gene partition in the analysis under Akaike Information Criterion (AIC) (12S, COI, CAD = GTR+I+G; *wingless* = K80+I+G). Bayesian analysis was performed using Mr. Bayes ver. 3.1.2 (Ronquist & Huelsenbeck 2003) submitted remotely to the Cyberinfrastructure for Phylogenetic Research Science Gateway V. 3.3 (<http://www.phylo.org/index.php/portal/>). The Monte Carlo Markov Chain (MCMC) method was used with the default analysis settings. Four chains (three hot, one cold) were run simultaneously for 1×10^7 generations, with tree sampling occurring every 1000 generations. The first 2500 sample generations were discarded as burn-in. The full dataset and MrBayes command block used are available from the Dryad Digital Repository (<http://dx.doi.org/10.5061/dryad.nn20r>).

Results

12S rRNA

Sequence data were acquired for 41 taxa. After alignment, a total of 544 bp were analysed, of which 195 (35.8%) were parsimony informative. Parsimony analysis returned 29 most parsimonious trees (726 steps, CI=0.474, RI=0.646), from which a strict consensus tree was constructed (Fig. A1 in the Appendix).

COI

Sequence data were acquired for 40 taxa. After alignment a total of 1495 bp were analysed, of which 540 (36.1%) were parsimony informative. Parsimony analysis returned 15 most parsimonious trees (3206 steps, CI=0.289, RI=0.483), from which a strict consensus tree was constructed (Fig. A2 in the Appendix).

wingless

Sequence data were acquired for 31 taxa, however the sequence length varied widely between specimens, and a paralog of *wingless* was found to have been sequenced for Micropezinae. The three micropezine taxa were excluded from the analysis and *Globopeza venezuelensis* was selected as the outgroup taxon. After alignment, a total of 556 bp were analysed for 28 taxa, of which 135 (24.3%) were parsimony informative. Parsimony analysis returned 24 most parsimonious trees (418 steps, CI=0.583,

RI=0.668), with which a strict consensus tree was constructed (Fig. A3 in the Appendix).

CAD

Sequence data were acquired for 37 taxa, with a total of 2110 bp analysed, of which 713 (33.8%) were parsimony informative. Parsimony analysis returned four most parsimonious trees (3131 steps, CI=0.382, RI=0.515), from which a strict consensus tree was constructed (Fig. A4 in the Appendix).

Concatenated molecular dataset

DNA sequence data were included from a total of 45 taxa, combining for a total of 4705 bp, 1583 (33.6%) of which were parsimony informative. Maximum parsimony analysis returned 72 most parsimonious trees (7650 steps, CI=0.382, RI=0.515), from which a strict consensus tree was constructed (Fig. 1).

Bayesian inference analysis

The MCMC chains reached stationarity (split frequencies <0.05) by 436 000 generations (final standard deviation of split frequencies 0.0240, all parameter estimates asymptotic). A total of 7500 generation samples were used to create a majority-rule consensus tree with branch length estimates and posterior probabilities for each node mapped (Fig. 2).

Discussion

Despite weak backbone congruency between gene trees, *Grallomyia* was consistently returned as the sister group of a clade, hereafter referred to as *Taeniamptera* s.s., containing the generic type species *Taeniamptera trivittata* as well as *T. lasciva*. A clade containing *T. angulata*, *T. albbasis*, *T. vulgata*, *T. annulata*, *T. gorgonae* and *T. thiemi*, all of which were considered by Hennig (1934) and Steyskal (1968) to be *Taeniamptera*, was returned separately and is hereafter referred to as the *Taeniamptera annulata* clade. When the total molecular dataset was analysed, *Hemichaeta* was returned as the sister group to *Grallomyia+Taeniamptera* s.s., further complicating “*Taeniamptera*”.

The placement of *Hemichaeta* and *Grallomyia* in these analyses renders *Taeniamptera* non-monophyletic, leaving two possible solutions: synonymize *Hemichaeta* and *Grallomyia* with *Taeniamptera*, or restrict *Taeniamptera* to *Taeniamptera* s.s. and recognize the *Taeniamptera annulata* clade as a separate genus. A broad definition of *Taeniamptera* encompassing *Hemichaeta* and *Grallomyia* would result in a taxon that is very difficult to identify morphologically due to a suite of conflicting characters (shape of the maxillary palpus — parallel-sided in *Hemichaeta*, axe-shaped in *Taeniamptera* and *Grallomyia*; wing cell r_{4+5} — open to wing margin in the *Taeniamptera annulata* clade and *Grallomyia*, closed prior to wing margin in *Hemichaeta* and *Taeniamptera* s.s.; length of the sclerotized portion of the distiphallus apical to the phallic bulb — less than 50% of the

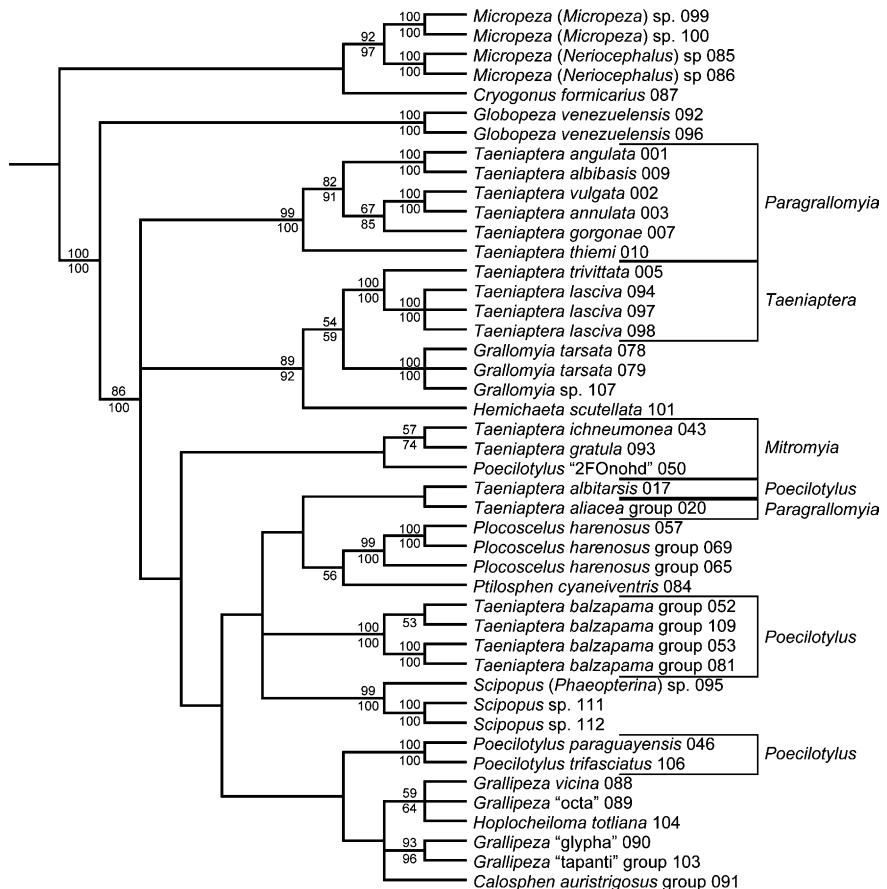

Fig. 1. Strict Consensus Tree for the *Taeniampterini* from concatenated DNA sequence dataset of four genes (12S, COI, wingless, CAD) (constructed from 72 most parsimonious trees; tree length=7650 steps, CI=0.382, RI=0.515). Nomenclature of taxon labels follows current published generic concepts (Steykal, 1968; Marshall, 2010; Marshall & Jackson, 2014). Numbers following taxon name indicate unique specimen identifiers for this study. New generic classifications proposed as a result of this study are indicated by labeled brackets. Numbers above nodes represent Bootstrap support, numbers below nodes represent Jackknife support.

length of the basal distiphallus in the *Taeniamptera annulata* clade and *Grallomyia*, greater than 50% of the length of the basal distiphallus in *Hemichaeta* and *Taeniamptera* s.s.).

Alternatively, *Taeniamptera* can be restricted to the *Taeniamptera trivittata* clade, requiring recognition of the species in the *Taeniamptera annulata* group as a separate genus. Hendel (1933) already provided a name for that group when he erected *Paragrallomyia* as a subgenus of *Grallomyia*, designating *Taeniamptera annulata* (as *Grallomyia*) as the type species. The elevation of *Paragrallomyia* to the generic level is the most acceptable option based on the taxa considered in this paper, since it breaks the former genus into two diagnosable clades, each with an existing name, while leaving the easily diagnosed taxa *Hemichaeta* and *Grallomyia* as separate genera. *Paragrallomyia* can be recognized

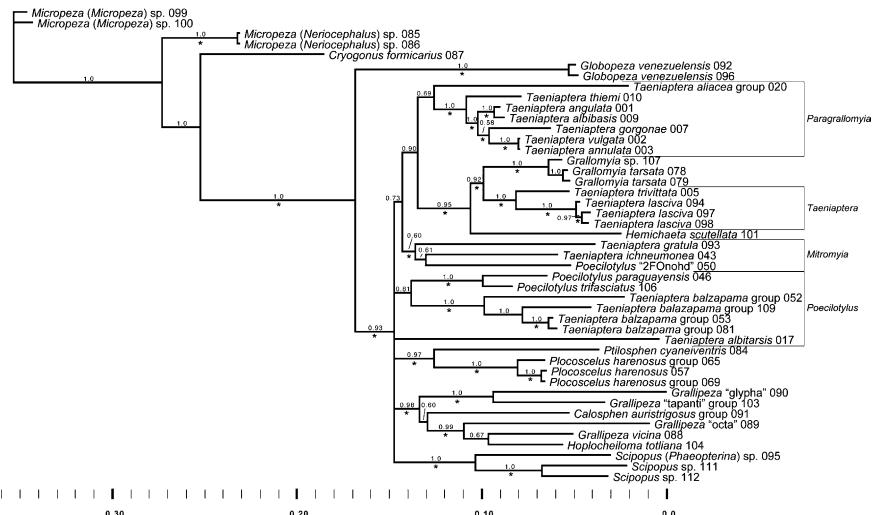

Fig. 2. Majority Rule Consensus cladogram from Bayesian Markov Chain Monte Carlo analysis of the Taeniapterini from concatenated DNA sequence dataset (12S, COI, wingless, CAD), including branch lengths, RI=0.483). Nomenclature of taxon labels follows current published generic concepts (Steykal, 1968; Marshall, 2010; Marshall & Jackson, 2014). Numbers following taxon name indicate unique specimen identifiers for this study. New generic classifications proposed as a result of this study are indicated by labeled brackets. Numbers at each node represent posterior probabilities. *Nodes recovered in the maximum parsimony analysis (Fig. 1).

morphologically by an axe-shaped maxillary palpus, wing cell r_{4+5} open to the wing margin, and by the presence of at least one dorsocentral bristle.

Hemichaeta scutellata is currently the only species placed in *Hemichaeta* (Marshall & Jackson 2014). A relationship between *Hemichaeta* and *Taeniaptera* is suggested by some morphological characters including wing venation (R_{4+5} and M_{1+2} converging well before the wing margin, forming a closed cell r_{4+5}) and distiphallus proportions and shape (portion distal to the phallic bulb more than 50% length of the segment basal to the phallic bulb and strongly hooked towards the posterior). Neither of these character states are present in *Grallomyia* (wing cell r_{4+5} open to the wing margin; distiphallus beyond bulb much shorter than basal portion, not strongly hooked towards the posterior). *Grallomyia* is currently monotypic, although at least one further species awaits description. Marshall (2010) recognized *Grallomyia* as a distinct genus in his key to Neotropical Micropezidae, and we support that nomenclatural decision here.

Our data show that, as expected, some species previously considered to be in *Taeniaptera* are misplaced. Among the species included in this analysis, *Taeniaptera albitalis* was consistently found to be widely separated from the *Taeniaptera* *Paragrallomyia* clade despite a superficial similarity to *Paragrallomyia* species. We propose a transfer of *Taeniaptera albitalis* to *Poecilotylus* to reflect this relationship, while at the same time recognizing that *Poecilotylus* is currently a paraphyletic assemblage of unplaced species and is in need of revision. The *Taeniaptera aliacea* group specimen we

included was returned outside of *Taeniamptera/Paragrallomyia* in the maximum parsimony analysis, but as sister to *Paragrallomyia* using Bayesian inference. Until this species complex can be further studied, we propose retaining it in *Paragrallomyia*.

Taeniamptera gratula was also recovered outside of the *Taeniamptera/Paragrallomyia* clade, along with *Taeniamptera ichneumonea* and a similar undescribed species. These species, along with *Taeniamptera grata* Wulp, 1897, *T. wulpi* Steyskal, 1967 and *T. feei* Steyskal 1986 form a distinctive clade that keys out with *Poecilotylus* in Marshall (2010); however, there is an available name that applies to this clade, *Mitromyia* Cresson 1930 (type species *Mitromyia conifer* Cresson 1930 = *Calobata grata* Wulp 1897). Steyskal (1967, 1986) considered *Taeniamptera grata*, *T. gratula*, *T. wulpi*, and later *Taeniamptera feei* to form a well-defined group characterized by unusual posterodorsal humps on the head, as well as synapomorphic male genital characters (Steyskal 1986), and stated “Should further investigation of the large and multifarious genus *Taeniamptera* lead to means of defining and delimiting distinct genera, then *Mitromyia* may be found to deserve generic rank” (1986: p. 175). We agree, and therefore resurrect *Mitromyia* to include *Taeniamptera grata*, *T. gratula*, *T. wulpi*, *T. feei* and *T. ichneumonea*.

Poecilotylus sensu Marshall (2010) was recovered as paraphyletic, as predicted by Marshall (2010), including two or three distinct species groups depending on analysis method. *Poecilotylus* is currently a convenient repository for Taeniampterini that do not fit into defined monophyletic taxa such as *Taeniamptera* ss, *Paragrallomyia*, *Grallomyia*, *Hemichaeta*, *Plocoscelus*, or *Ptilosphen*. All nomenclatural changes proposed as a result of these analyses can be found in Table 3.

The *Grallipeza* species included in these analyses displayed considerable variation in their phylogenetic positions. The four species included in this analysis represent disparate species groups of what is currently considered *Grallipeza*, a genus currently undergoing a full revision to complement Marshall’s Caribbean clade revision (2013). *Grallipeza* and *Calosphen* together represent a taxonomic mire similar to the *Taeniamptera/Poecilotylus* problem examined in this study, as neither genus is currently adequately defined or consistently diagnosable.

Our data do not support the tribal classifications proposed by Cresson (1938) and Aczél (1951), with the Taeniampterini rendering the Rainieriini/Grallipezini paraphyletic, however they remain a convenient shorthand for the division of the subfamily Taeniampterinae into two phenetic groups based on distinctive wing venation characters. We suggest the retention of these tribes for now, with the full expectation that further phylogenetic analysis of the subfamily will provide additional evidence that one or both tribes are an artificial group.

Acknowledgements

The authors would like to thank Scott Kelso and Joel Gibson for assistance with lab work and DNA sequence acquisition, as well as Joel Kits, Gil Gonçalves-Miranda, Andrew Young and Steve Paiero for general help with phylogenetics and discussions

Table 3. Changes to generic nomenclature of the Taeniampterini based on phylogenetic relationships.

<i>Mitromyia</i> Cresson, 1930 resurrected from synonymy
